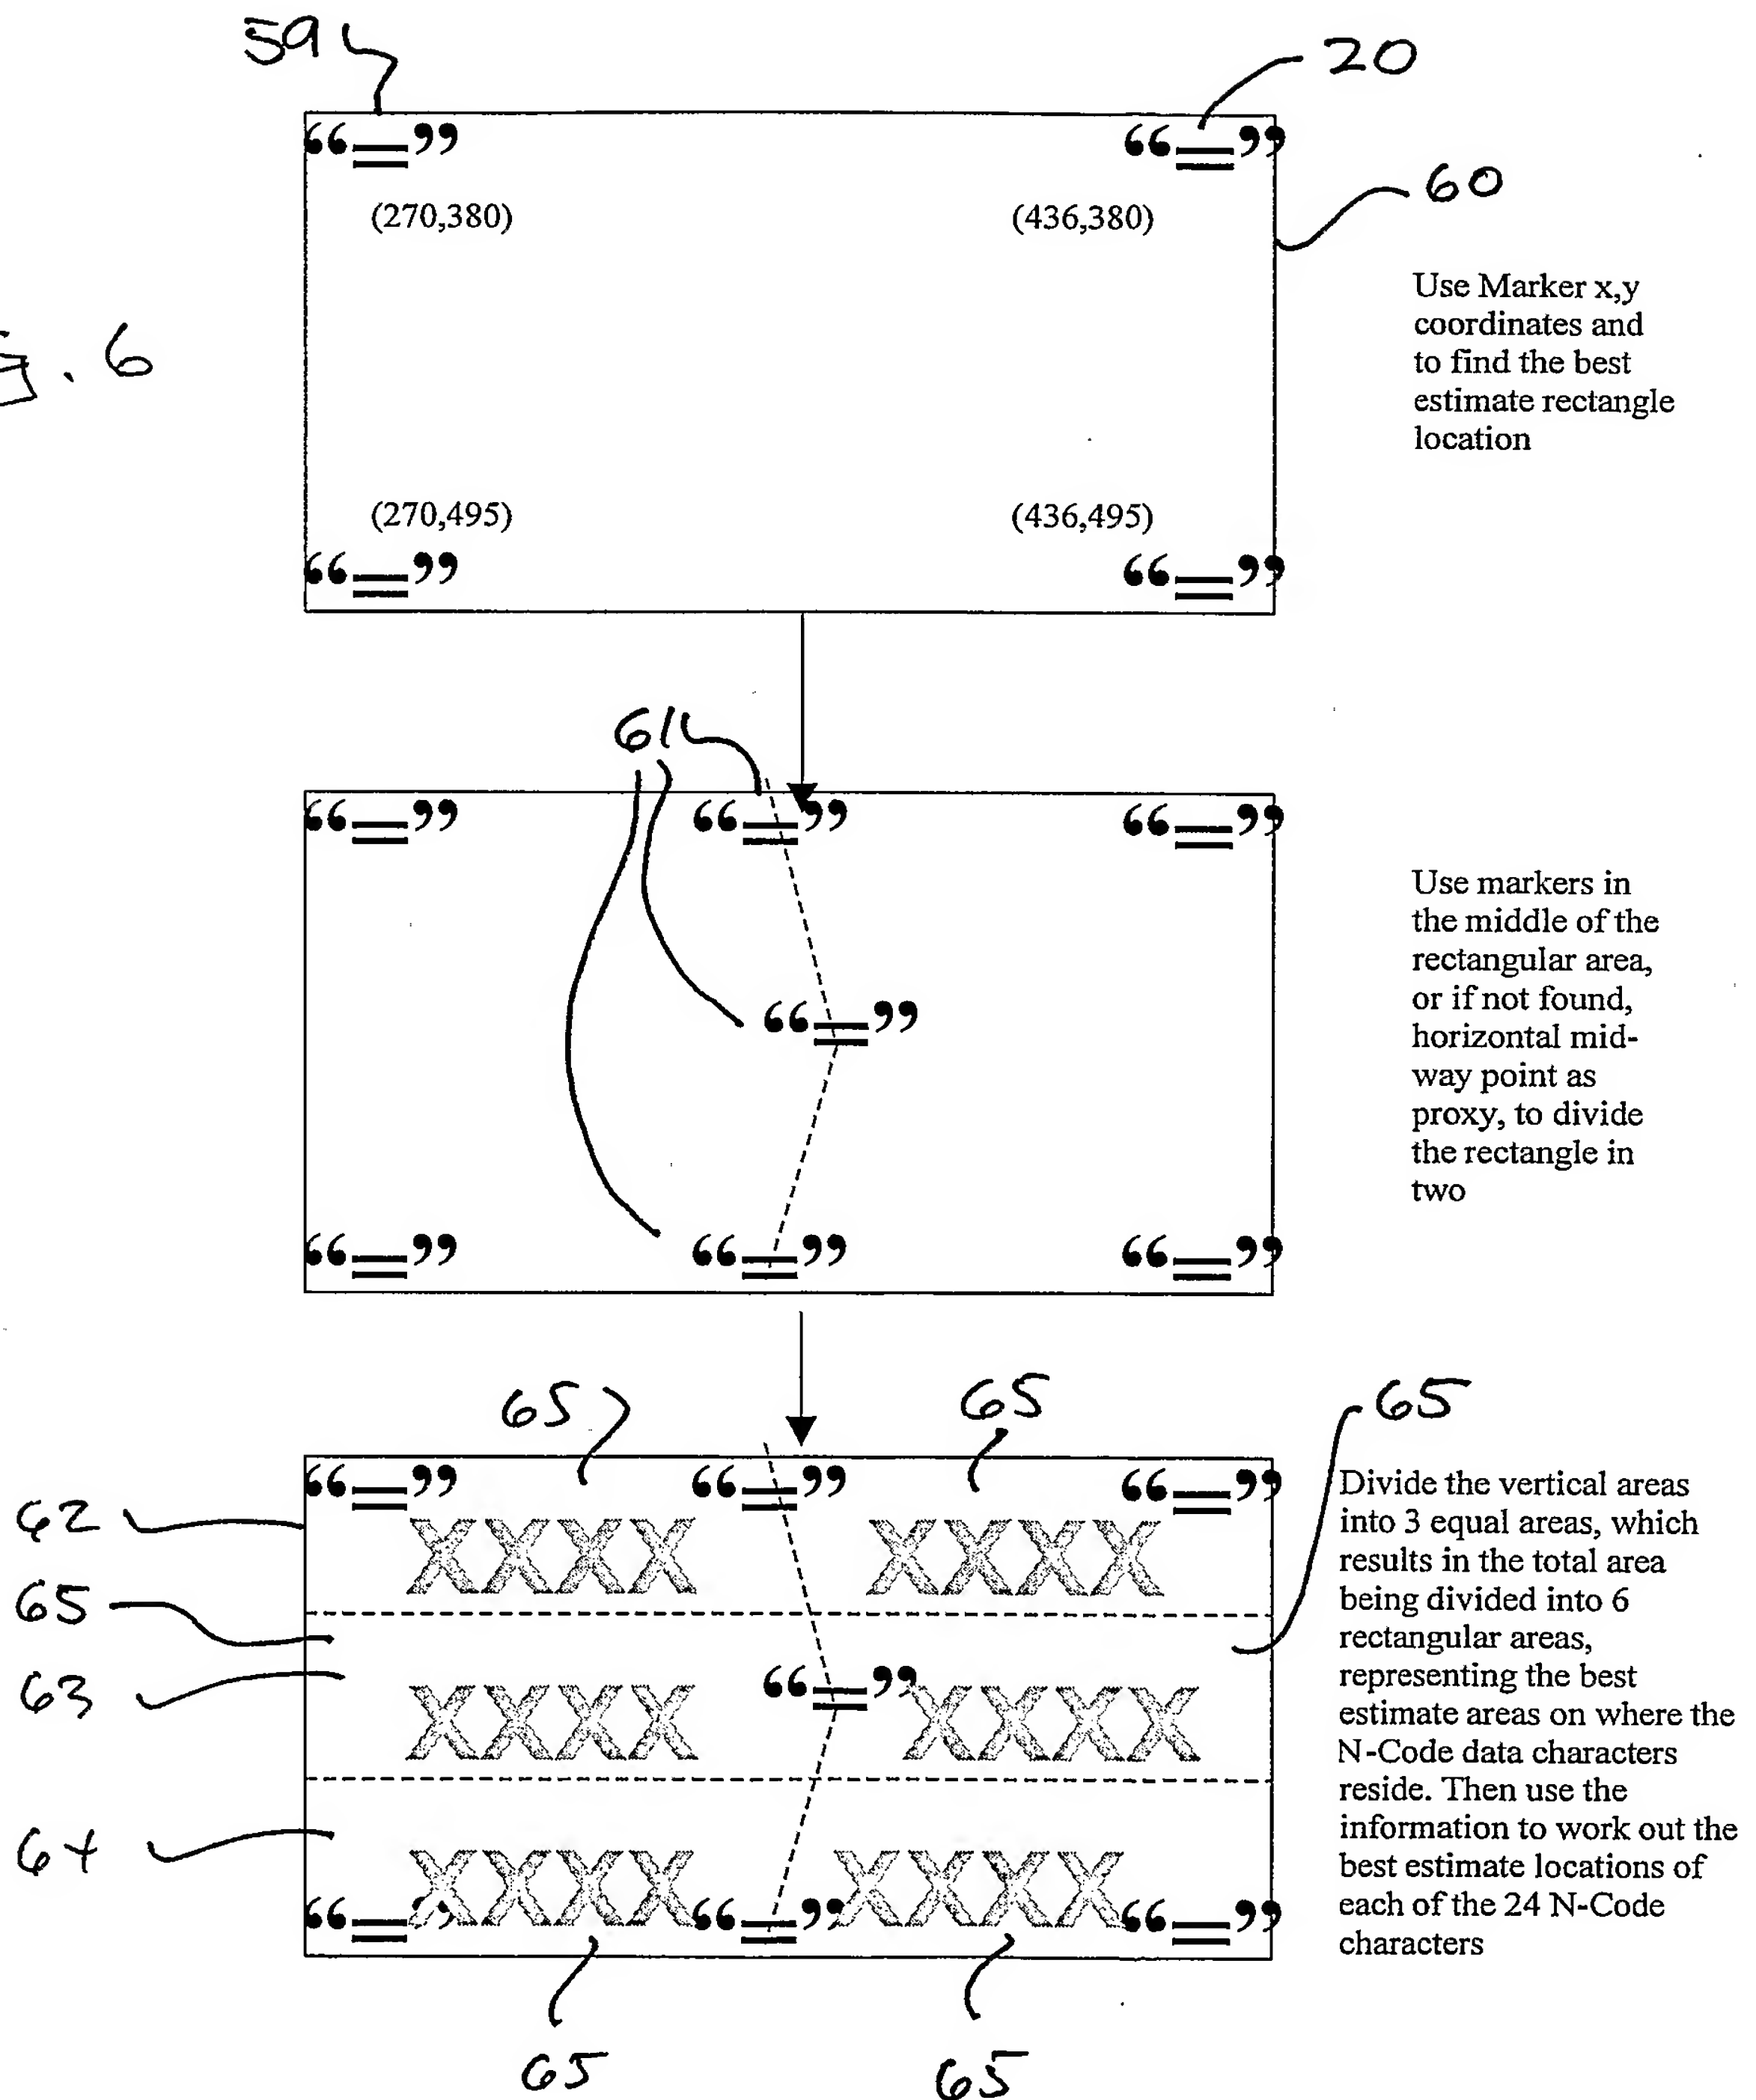

Fig. 6

The algorithm determines the closest character returned by the OCR output (denoted by data characters starting with 6, U, etc) to each of the expected character positions (X, X, X, etc), and use that as the best estimate

In this instance, EJCG will be selected in favour of other surrounding “garbage” characters.

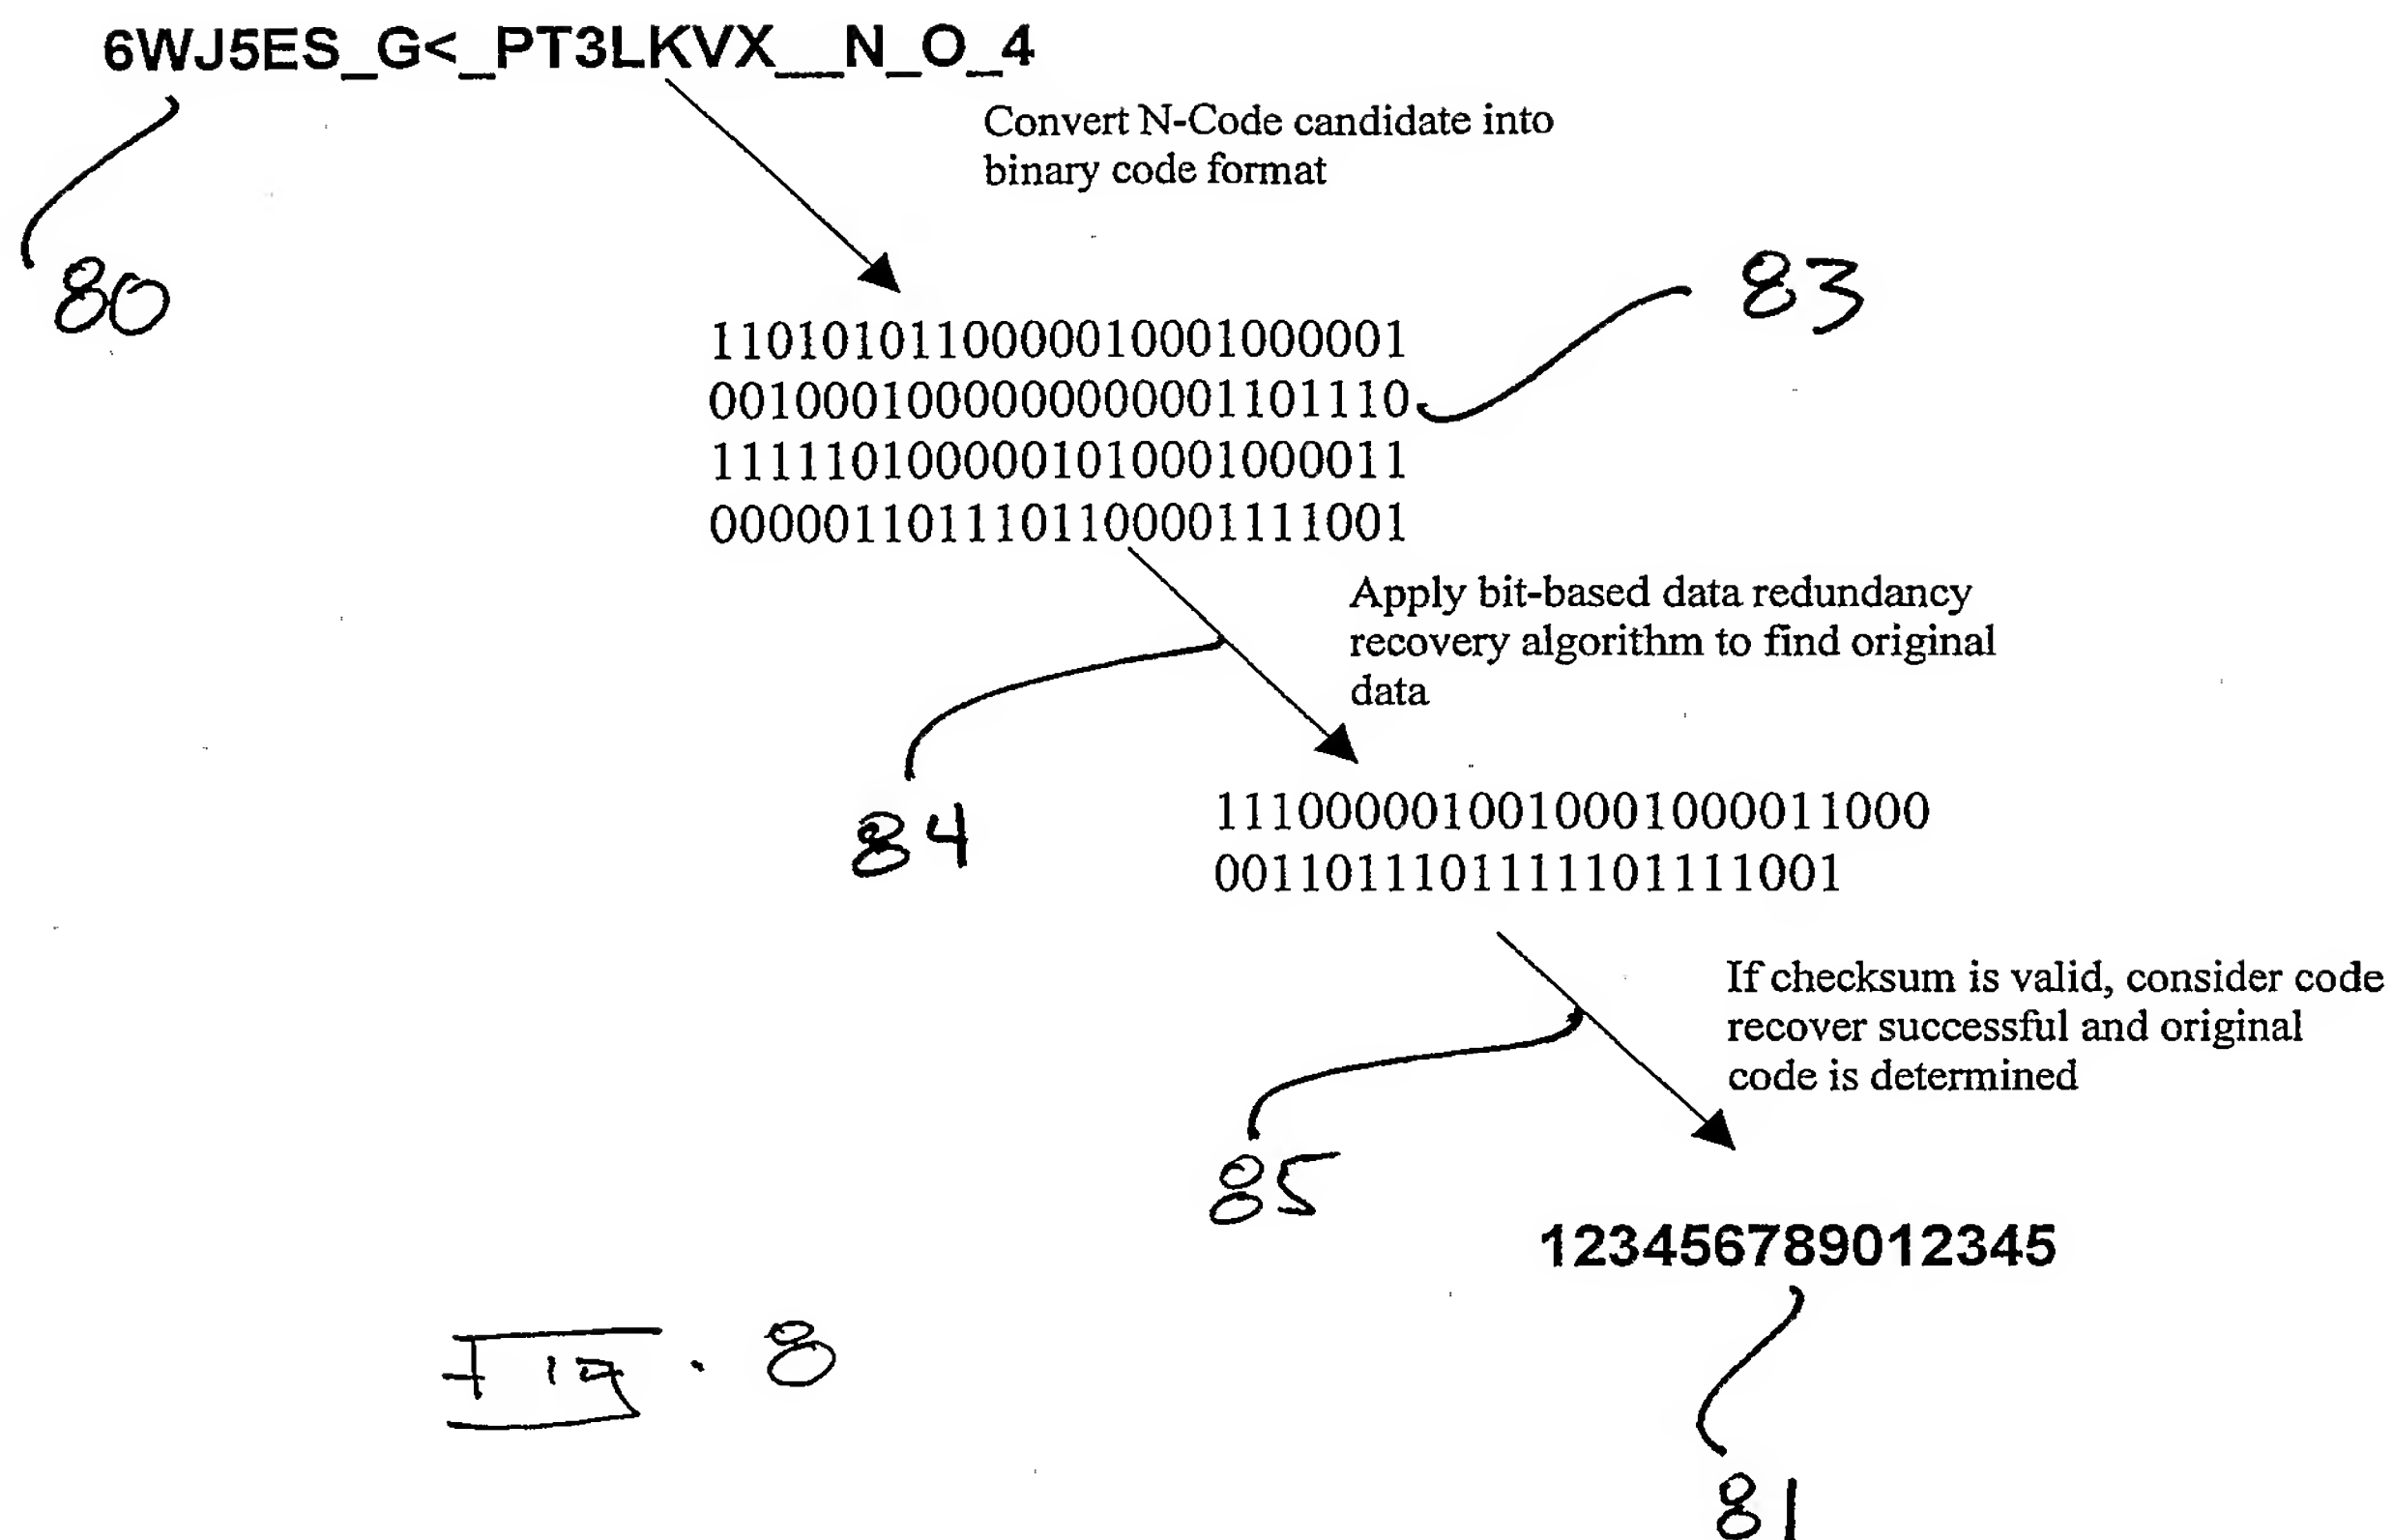

In this instance, the algorithm helps the engine to use <_PT, and pass in the 2nd character as unknown, rather than using thinking <PT3 is the sequence. As <5PT is the actual sequence, this algorithm helps the engine know that it cannot determine what was in the second character, rather than getting 3 wrong with a <PT3 guess – as they will be misplaced

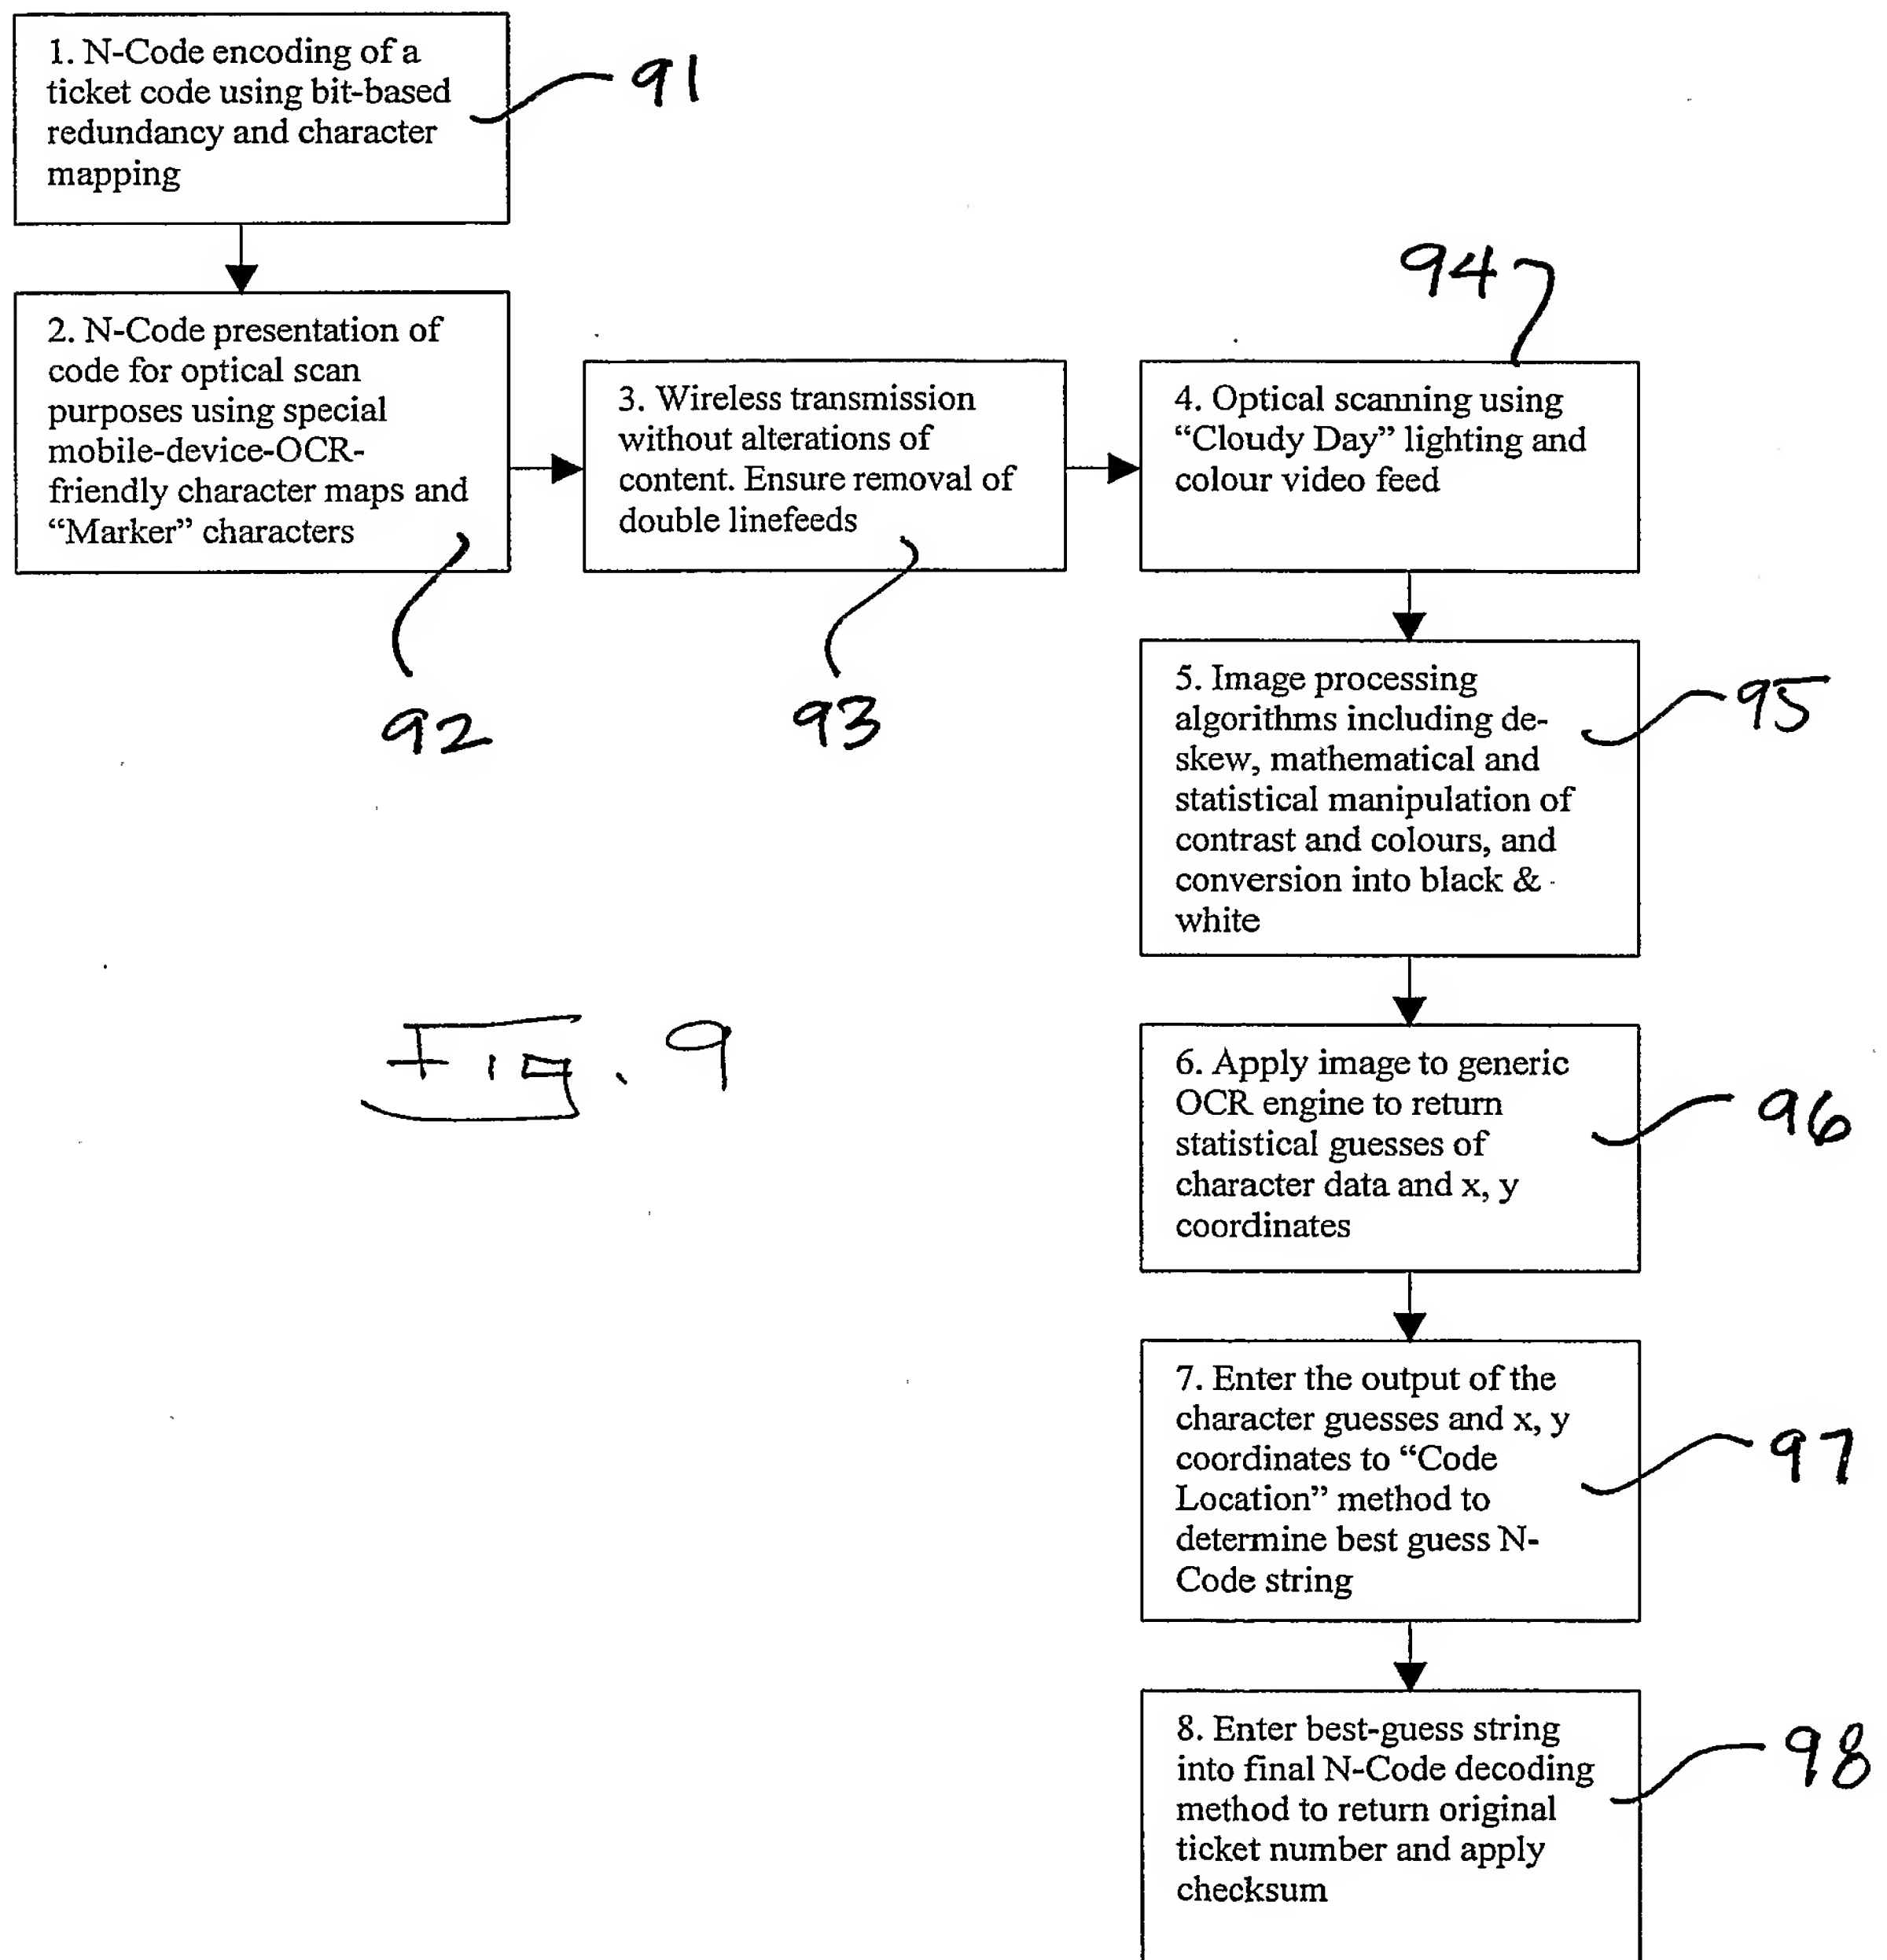

In general, this code-location algorithm helps the engine decide whether a character is there, or missing, and how likely is it to be correct, based on its distance away from the expected location. Also it helps the engine determine the best guess of the 4 data characters, rather than having to examine strings that are longer than 4 characters and be confused which 4 to pass on to the next step
